CPSC 340:
Machine Learning and Data Mining

Probabilistic Classification

Admin

- Assignment 1 is due Monday: you should be almost done, and ideally have submitted one version already.
  - You can use 1 late class to submit on Wednesday, 2 for Friday.
  - But you probably shouldn't for the first HW!

Last Time: Training, Testing, and Validation

- Training step:

  Input: set of 'n' training examples x_i with labels y_i

  Output: a model that maps from arbitrary x_i to a $\hat{y}_i$

- Prediction step:

  Input: set of 't' testing examples $\tilde{x}_i$ and a model.

  Output: predictions $\hat{y}_i$ for the testing examples.

- What we are interested in is the test error:
  - Error made by prediction step on new data.

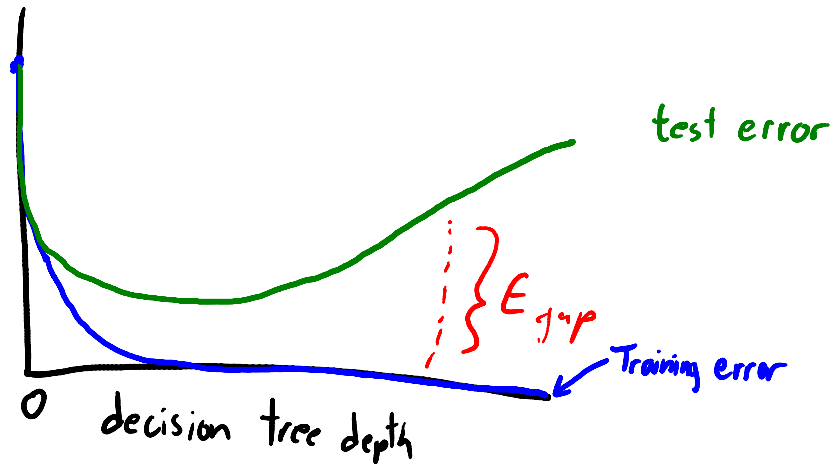
Last Time: Fundamental Trade-Off

- We decomposed test error to get a fundamental trade-off:

$$E_{test} = E_{gap} + E_{train}$$

"test error" "generalization gap" "training error"

  - Where $E_{gap} = (E_{test} - E_{train})$.



- E_{train} goes down as model gets complicated:
  - Training error goes down as a decision tree gets deeper.
- But E_{gap} goes up as model gets complicated:
  - Training error becomes a worse approximation of test error.

Last Time: Validation Error

- Key principle: we cannot let test data influence training.
- But we can approximate E_{test} with a validation error:
  - Error on a set of training examples we "hid" during training.

  - Find the decision tree based on the "train" rows.
  - Validation error is the error of the decision tree on the "validation" rows.
    - We typically choose "hyper-parameters" like depth to minimize the validation error.

Train/Validation/Test Terminology

- Training set: used (a lot) to set parameters.
- Validation set: used (a few times) to set hyper-parameters.
- Testing (Test) set: used (once) to evaluate final performance.
- Deployment (real-world): what you really care about.

	`fit`	`score`	`predict`
Train	✓	✓	✓
Validation		✓	✓
Test		once	once
Deployment			✓

Optimization Bias

- Another name for *overfitting* is "optimization bias":
  - How biased is an "error" estimate?

- Optimization bias of parameter learning:
  - During learning, we could search over tons of different decision trees.
  - So we can get "lucky" and find one with low training error by chance.
    - "Overfitting of the training error".

- Optimization bias of hyper-parameter tuning:
  - Here, we might optimize the validation error over 20 values of "depth".
  - One of the 20 trees might have low validation error by chance.
    - "Overfitting of the validation error".

Overfitting to the Validation Set?

- We can overfit to the validation set (common in practice):
  - Validation error is only an unbiased approximation if you use it once.
  - Once you start optimizing it, you start to overfit to the validation set.

- But validation error usually has lower optimization bias than train error.
  - Might optimize over 20 values of "depth", instead of millions+ of possible trees.
    - Amount of overfitting to validation set is low if we only try 10 things.

- Optimization bias is larger when the validation set is "small":
  - The optimization bias decreases as the number of validation examples increases.

- Remember, our goal is still to do well on the test set (new data), not the validation set (where we already know the labels).

Should you trust them?

- Scenario 1:
  - "I built a model based on the data you gave me."
  - "It classified your data with 98% accuracy."
  - "It should get 98% accuracy on the rest of your data."

- Probably not:
  - They are reporting training error.
  - This might have nothing to do with test error.
  - E.g., they could have fit a very deep decision tree.
- Why 'probably'?
  - If they only tried a few very simple models, the 98% might be reliable.
  - E.g., they only considered decision stumps with simple 1-variable rules.

Should you trust them?

- Scenario 2:
  - "I built a model based on half of the data you gave me."
  - "It classified the other half of the data with 98% accuracy."
  - "It should get 98% accuracy on the rest of your data."

- Probably:
  - They computed the validation error once.
  - This is an unbiased approximation of the test error.
  - Trust them if you believe second half of data did not influence training.

Should you trust them?

- Scenario 3:
  - "I built 10 models based on half of the data you gave me."
  - "One of them classified the other half of the data with 98% accuracy."
  - "It should get 98% accuracy on the rest of your data."

IID

- Probably:
  - They computed the validation error a small number of times.
  - Maximizing over these errors is a biased approximation of test error.
  - But they only maximized it over 10 models, so bias is probably small.
  - Probably know key principle of not letting test data influence training.

Should you trust them?

- Scenario 4:
  - "I built 1 billion models based on half of the data you gave me."
  - "One of them classified the other half of the data with 98% accuracy."
  - "It should get 98% accuracy on the rest of your data."

- Probably not:
  - They computed the validation error a huge number of times.
  - They tried so many models, one of them is likely to work by chance.
- Why 'probably'?
  - If the 1 billion models were **all** extremely-simple, 98% might be reliable.

Should you trust them?

- Scenario 5:
  - "I built 1 billion models based on the first third of the data you gave me."
  - "One of them classified the second third of the data with 98% accuracy."
  - "It also classified the last third of the data with 98% accuracy."
  - "It should get 98% accuracy on the rest of your data."

- Probably:
  - They computed the first validation error a huge number of times.
  - But they had a second validation set that they only looked at once.
  - The second validation set gives unbiased test error approximation.
  - This is ideal, as long last third is not influencing training.
  - And assuming you are using IID data in the first place.

Validation Error and Optimization Bias

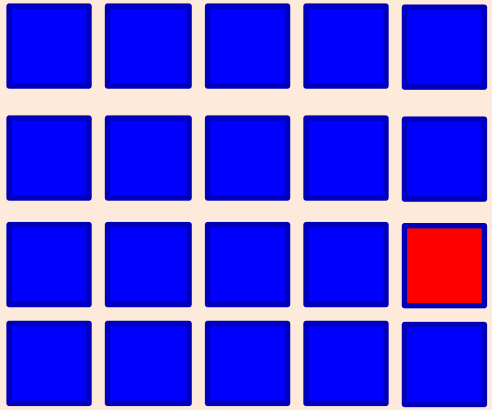
- Optimization bias is small if you only compare a few models:
  - Best decision tree on the training set among depths 1, 2, 3,…, 10.
  - Risk of overfitting to validation set is low if we try 10 things.

- Optimization bias is large if you compare a lot of models:
  - All possible decision trees of depth 10 or less.
  - Here we're using the validation set to pick between a billion+ models:
    - Risk of overfitting to validation set is high: could have low validation error by chance.
  - If you did this, you might want a second validation set to detect overfitting.

- And optimization bias shrinks as you grow size of validation set.

Aside: Optimization Bias leads to Publication Bias

- Suppose that 20 researchers perform the exact same experiment:

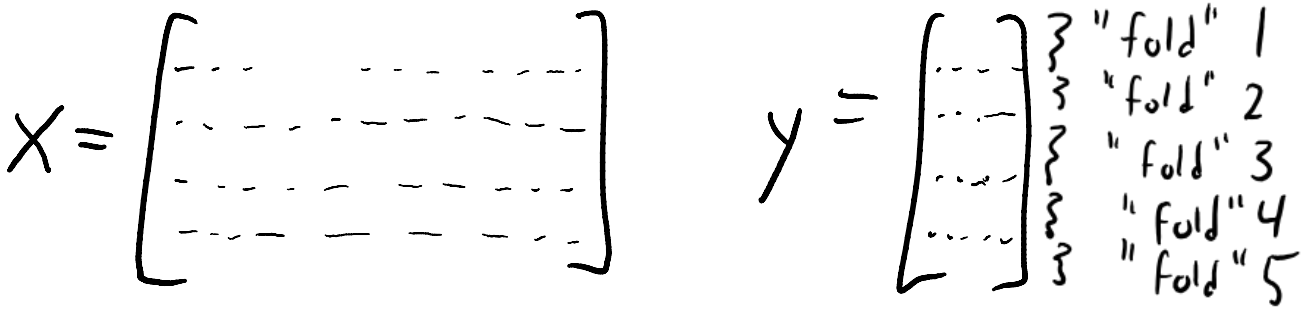


- They each test whether their effect is “significant” ($p < 0.05$).
  - 19/20 find that it is not significant.
  - But the 1 group finding it’s significant publishes a paper about the effect.

- This is again optimization bias, contributing to publication bias.
  - A contributing factor to many reported effects being wrong.

Cross-Validation (CV)

- Isn't it wasteful to only use part of your data?
- 5-fold cross-validation:
  - Train on 80% of the data, validate on the other 20%.
  - Repeat this 5 times with the different splits, and average the score.



1. Train on folds $\{1,2,3,4\}$, compute error on fold 5.
2. Train on folds $\{1,2,3,5\}$, compute error on fold 4.
3. Train on folds $\{1,2,4,5\}$, compute error on fold 3.

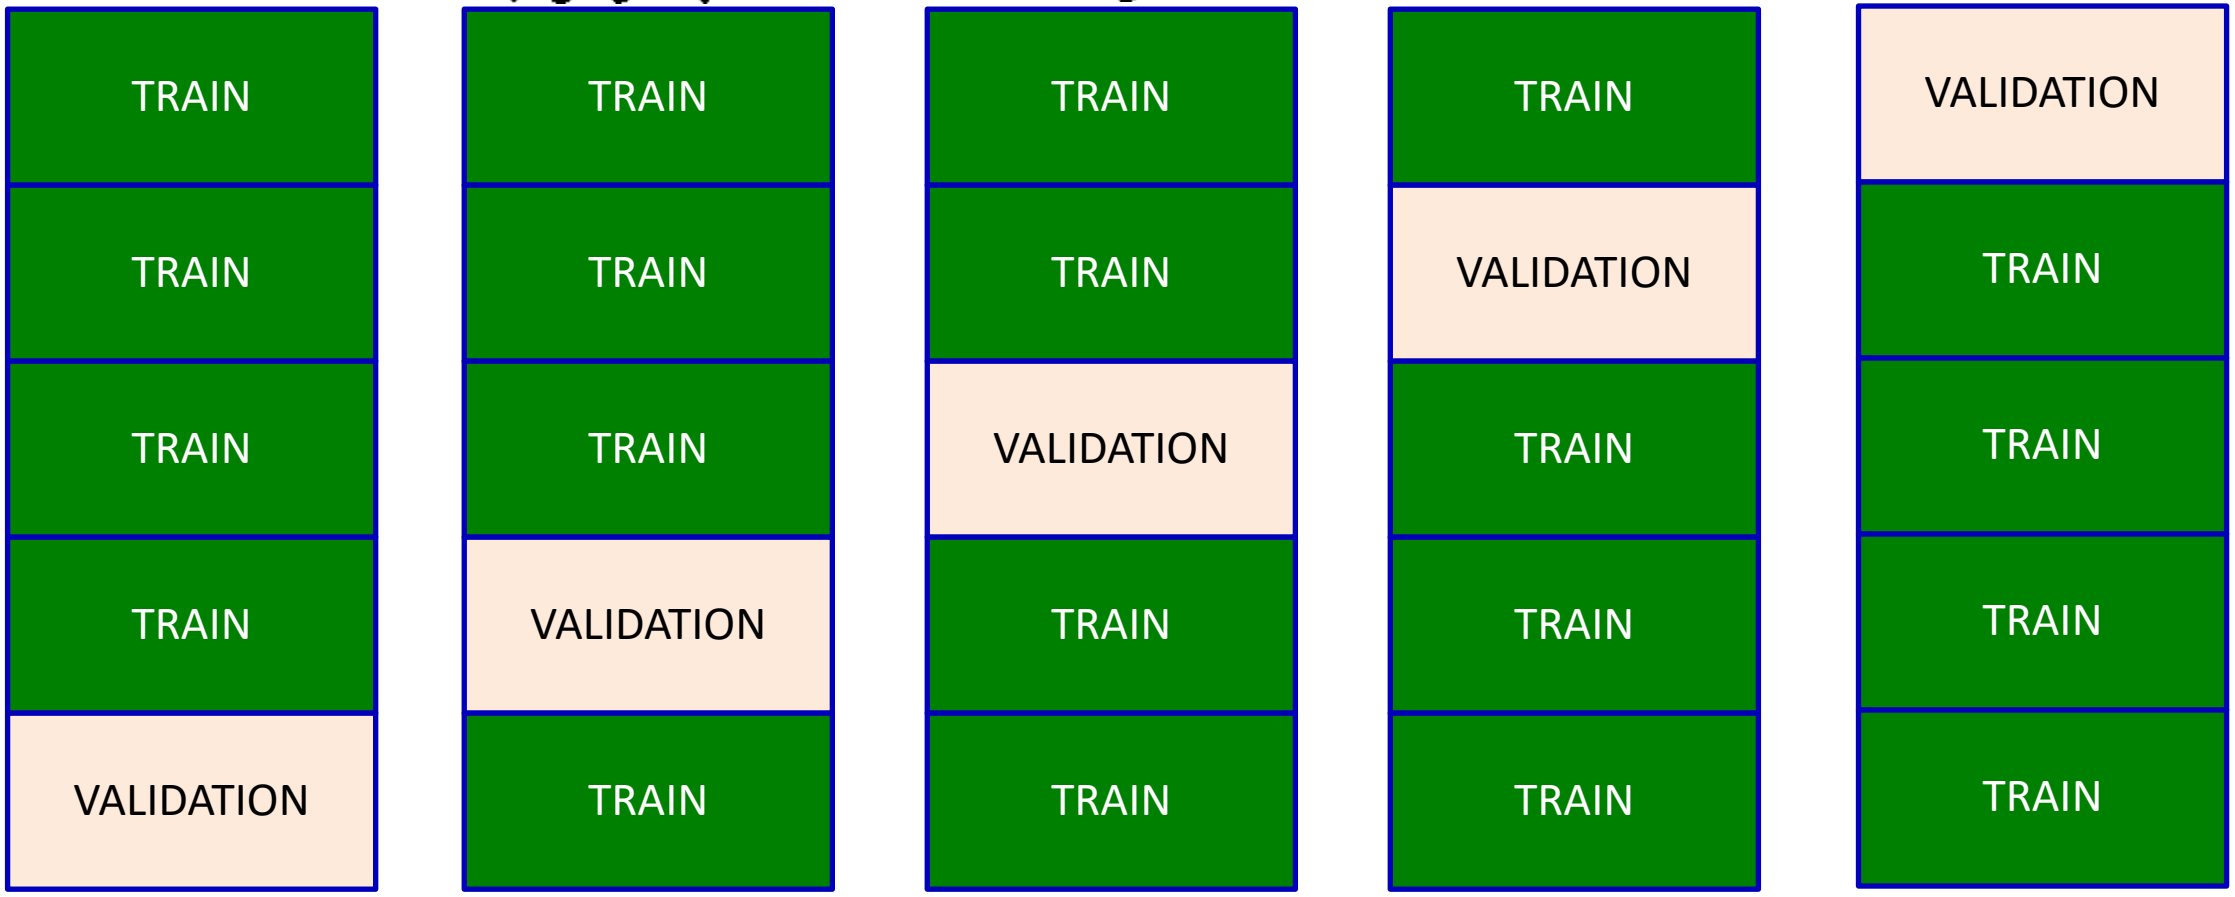
⋮

6. Take average of the 5 errors as approximation of test error

Cross-Validation (CV)

Not in dev? Learn

You would have different hyper Param each time



CV error estimate for this hyper-parameter: mean(errors) = 0.16

Cross-Validation Pseudo-Code

To choose depth

```
for depth in 1:20
    compute cross-validation score
return depth with highest score
```

To compute 5-fold cross-validation score:

```
for fold in 1:5
    train 80% that doesn't include fold
    test on fold
return average test error
```

Notes:

- This fits 100 models! (20 depths times 5 folds)
- We get one (average) score for each of the 20 depths.
- This procedure only picks the depth.
  - ↳ You might then train on the whole dataset with the chosen depth.

Cross-Validation (CV)

- You can take this idea further ("k-fold cross-validation"):
  - 10-fold cross-validation: train on 90% of data and validate on 10%.
    - Repeat 10 times and average (test on fold 1, then fold 2,…, then fold 10),
  - Leave-one-out cross-validation: train on all but one training example.
    - Repeat n times and average.
- Gets more accurate but more expensive with more folds.
  - To choose depth we compute the cross-validation score for each depth.

- As before, if data is ordered then folds should be random splits.
  - Randomize first, then split into fixed folds.

Next Topic: Probabilistic Classifiers

The “Best” Machine Learning Model

- Decision trees are not always most accurate on test error.
- What is the “best” machine learning model?
  - Measured as the test (or generalization) error (average error for a new IID (x, y), or "How well we expect to do on a completely fresh test set").
- No free lunch theorem (proof in bonus slides):
  - There is **no** “best” model achieving the best generalization error for every problem.
  - If model A generalizes better to new data than model B on one dataset, there is another dataset where model B works better.

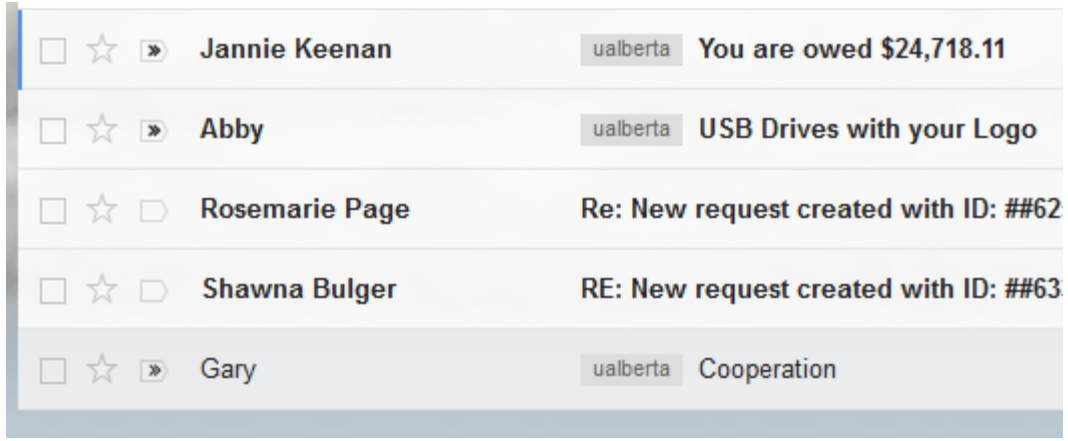
The “Best” Machine Learning Model

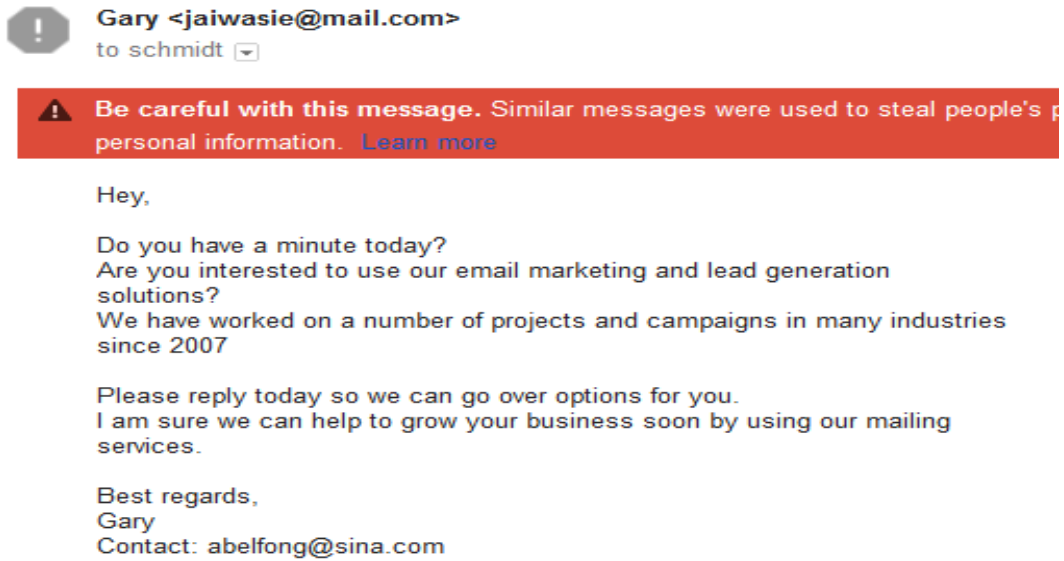
- Implications of the lack of a “best” model:
  - We need to learn about and try out multiple models.
- So which ones to study in CPSC 340?
  - We’ll usually motivate each method by a specific application.
  - But we’re focusing on models that have been effective in many applications.

- Caveat of no free lunch (NFL) theorem:
  - The world is very structured.
    - But proof of the no-free-lunch theorem assumes any map from x_i to y_i is equally likely.
  - Some datasets are more likely than others.
  - Model A really could be better than model B on every real dataset in practice.
- Machine learning research:
  - Large focus on models that are useful across many applications.

Application: E-mail Spam Filtering

- Want a build a system that detects spam e-mails.
  - Context: spam used to be a big problem.



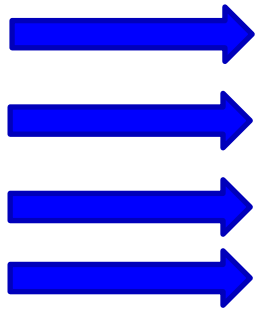


- Can we formulate as supervised learning?

Spam Filtering as Supervised Learning

- Collect a large number of e-mails, gets users to label them.

$	Hi	CPSC	340	Vicodin	Offer	…	Spam?
1	1	0	0	1	0	…	1
0	0	0	0	1	1	…	1
0	1	1	1	0	0	…	0
…	…	…	…	…	…	…	…



- We can use ($y_i = 1$) if e-mail 'i' is spam, ($y_i = 0$) if e-mail is not spam.
- Extract features of each e-mail (like bag of words).
  - ($x_{ij} = 1$) if word/phrase 'j' is in e-mail 'i', ($x_{ij} = 0$) if it is not.

Feature Representation for Spam

- Are there better features than bag of words?
  - We add bigrams (sets of two words):
    - “CPSC 340”, “wait list”, “special deal”.
  - Or trigrams (sets of three words):
    - “Limited time offer”, “course registration deadline”, “you’re a winner”.
  - We might include the sender domain:
    - <sender domain == “mail.com”>.
  - We might include regular expressions:
    - <your first and last name>
  - Now: embeddings from large language models.

Probabilistic Classifiers

- For years, best spam filtering methods used naïve Bayes.
  - A probabilistic classifier based on Bayes rule.
  - It tends to work well with bag of words.
  - Recently shown to improve on state of the art for CRISPR "gene editing" (link).

- Probabilistic classifiers estimate conditional probability $p(y_i \mid x_{i1}, x_{i2}, \ldots, x_{id})$.
  - "If a message has words $x_i = [x_{i1}, x_{i2}, \ldots, x_{id}]$, what is probability that message is spam?"
    - When we use commas (',') in probability statements, it should be read as an "AND".

- Classify it as spam if probability of spam is higher than not spam:
  - If $p(y_i = \text{"spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id}) > p(y_i = \text{"not spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id})$
    - return "spam".
  - Else
    - return "not spam".

Spam Filtering with Bayes Rule

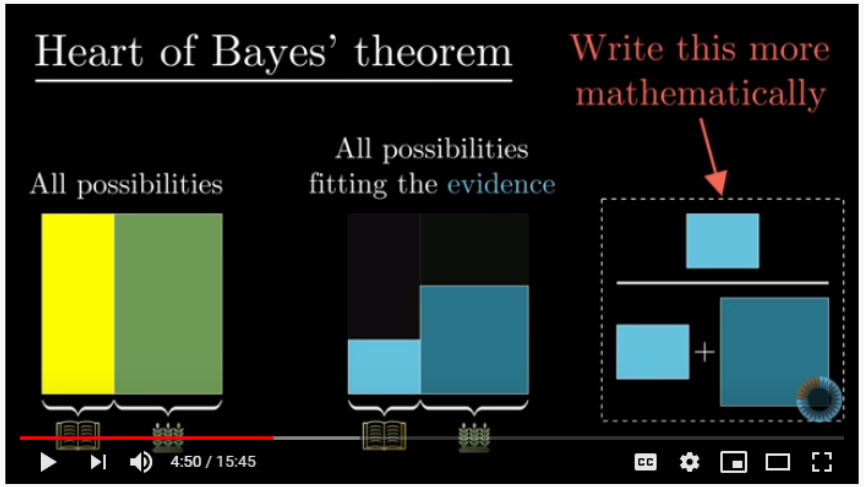
Baye's Theorem

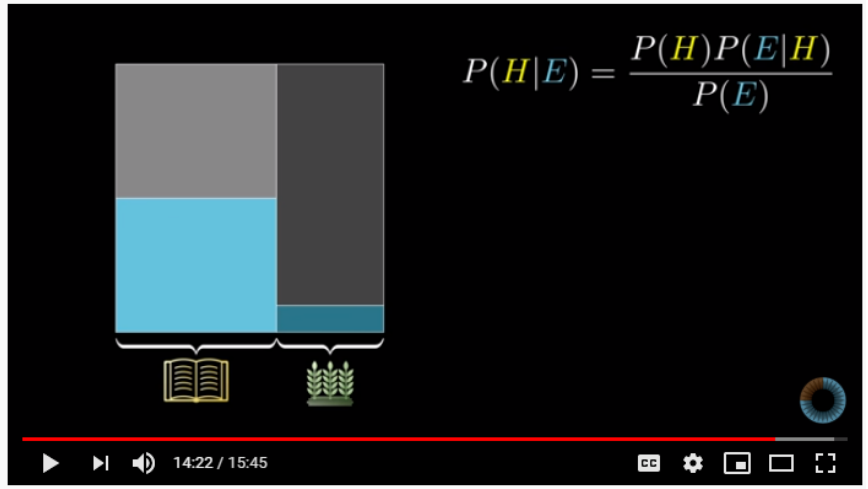
$$P(A \mid B) = \frac{P(B \mid A) \cdot P(A)}{P(B)}$$

- To model conditional probability, naïve Bayes uses Bayes rule:

$$p(y_i = \text{"spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id}) = \frac{p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"})\, p(y_i = \text{"spam"})}{p(x_{i1}, x_{i2}, \ldots, x_{id})}$$

- Nice video giving visual intuition for Bayes rule here:





Spam Filtering with Bayes Rule

- To model conditional probability, naïve Bayes uses Bayes rule:

$$p(y_i = \text{"spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id}) = \frac{p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"})\, p(y_i = \text{"spam"})}{p(x_{i1}, x_{i2}, \ldots, x_{id})}$$

- On the right we have three terms:
  - Probability $p(y_i)$ that an e-mail is spam.
  - Probability $p(x_{i1}, x_{i2}, \ldots, x_{id})$ that an e-mail has the set of words x_i.
  - Conditional $p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{“spam”})$ that spam e-mail has the words x_i.
    - And you need the same for non-spam e-mails.
- We do not know any of these probabilities.
  - We train the model by estimating these probabilities from training data.

Spam Filtering with Bayes Rule

$$p(y_i = \text{"spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id}) = \frac{p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"})\, p(y_i = \text{"spam"})}{p(x_{i1}, x_{i2}, \ldots, x_{id})}$$

- What do these terms mean?

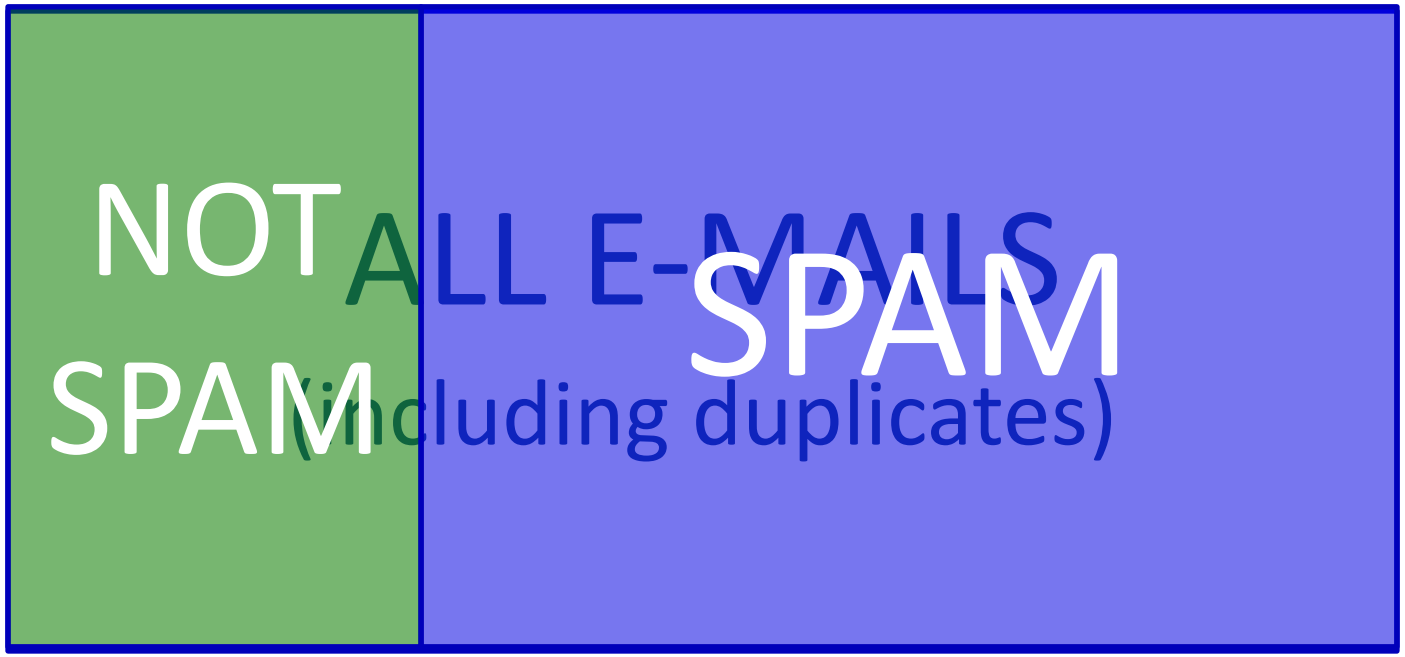
ALL E-MAILS

(including duplicates)

Spam Filtering with Bayes Rule

$$p(y_i = \text{"spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id}) = \frac{p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"})\, p(y_i = \text{"spam"})}{p(x_{i1}, x_{i2}, \ldots, x_{id})}$$

- $p(y_i$ = "spam") is probability that a random e-mail is spam.
  - This is easy to approximate from data: use the proportion in your data.



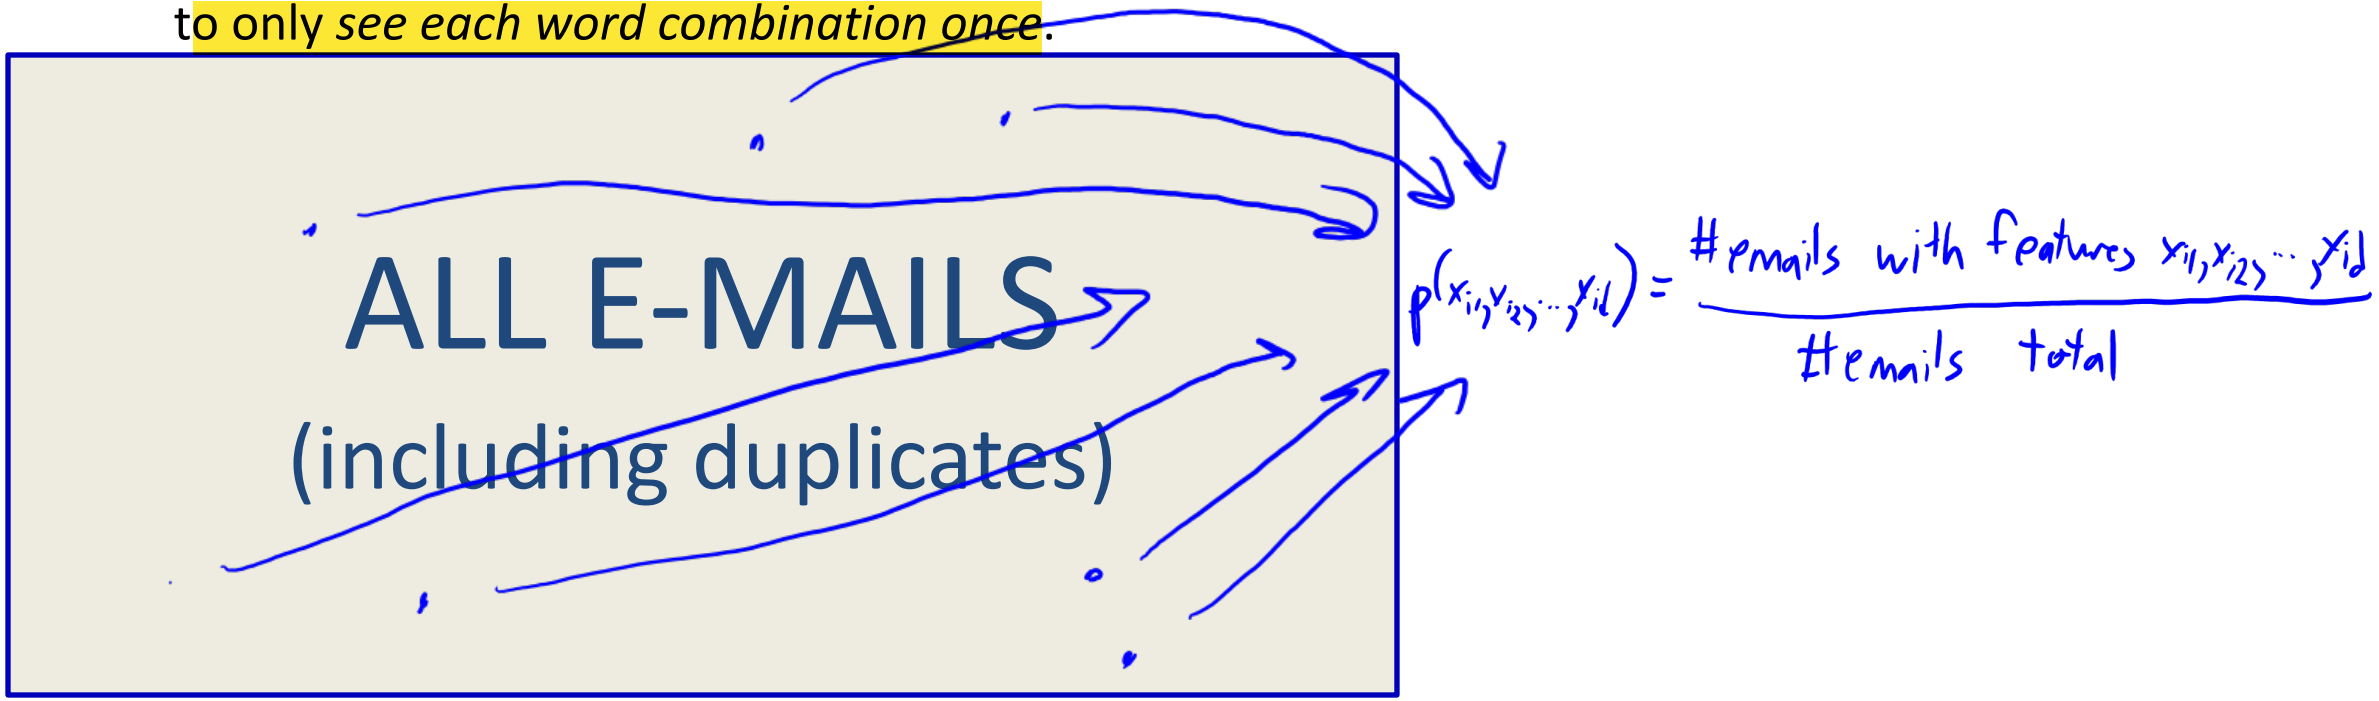
$$p(y_i = \text{"spam"}) = \frac{\#\text{ spam messages}}{\#\text{ total messages}}$$

This is an "estimate" of the true probability. In particular, this formula is a "maximum likelihood estimate" (MLE). We will cover likelihoods and MLEs later in the course.

Spam Filtering with Bayes Rule

$$p(y_i = \text{"spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id}) = \frac{p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"})\, p(y_i = \text{"spam"})}{p(x_{i1}, x_{i2}, \ldots, x_{id})}$$

- $p(x_{i1}, x_{i2}, \ldots, x_{id})$ is joint probability that a random e-mail has features x_i:
  - Hard to approximate: with 'd' words we need to collect 2^d "coupons",
    to only *see each word combination once*.



Spam Filtering with Bayes Rule

$$p(y_i = \text{"spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id}) = \frac{p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"})\, p(y_i = \text{"spam"})}{p(x_{i1}, x_{i2}, \ldots, x_{id})}$$

- $p(x_{i1}, x_{i2}, \ldots, x_{id})$ is joint probability that a random e-mail has features x_i :
  - Hard to approximate: with 'd' words we need to collect 2^d "coupons",
    but it turns out we can ignore it:

Naive Bayes returns "spam" if $p(y_i = \text{"spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id}) > p(y_i = \text{"not spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id})$

By Bayes rule this means $\frac{p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"})\, p(y_i = \text{"spam"})}{p(x_{i1}, x_{i2}, \ldots, x_{id})} > \frac{p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"not spam"})\, p(y_i = \text{"not spam"})}{p(x_{i1}, x_{i2}, \ldots, x_{id})}$

Multiply both sides by $p(x_{i1}, x_{i2}, \ldots, x_{id})$:

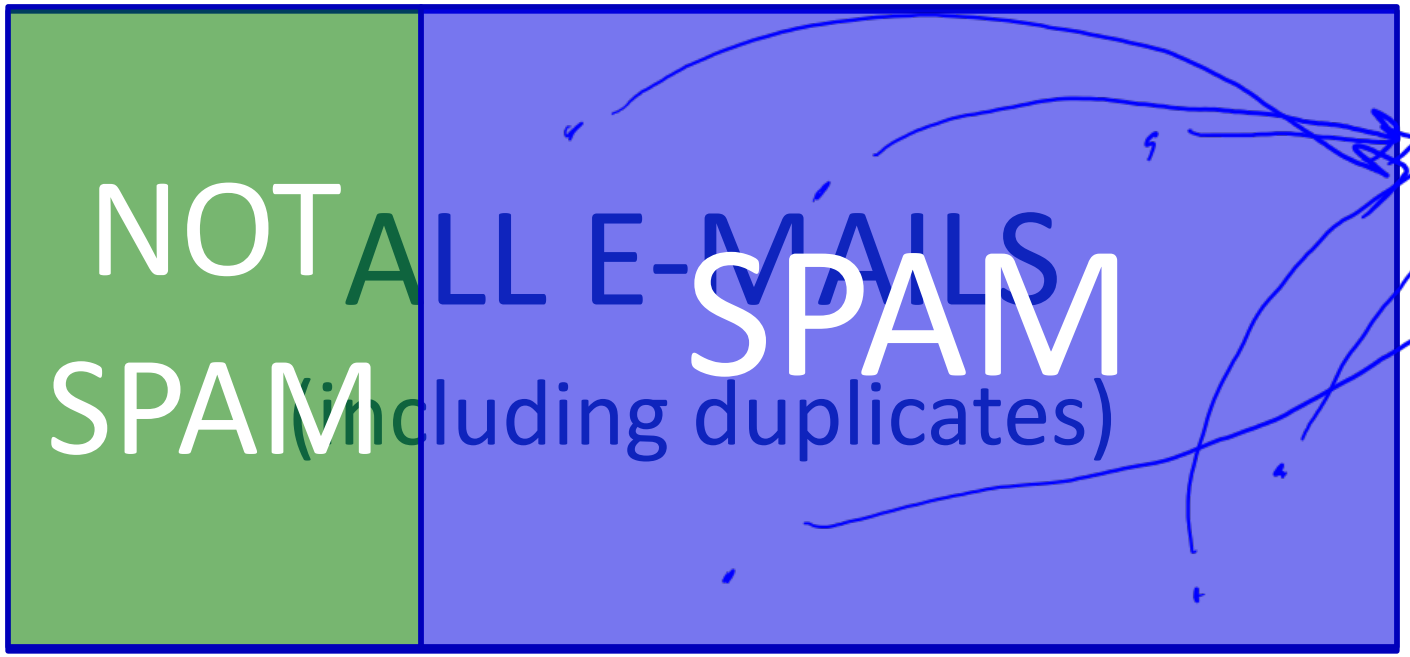
$$p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"})\, p(y_i = \text{"spam"}) > p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"not spam"})\, p(y_i = \text{"not spam"})$$

No need to know $p(x_{i1}, x_{i2}, \ldots, x_{id})$.

Spam Filtering with Bayes Rule

$$p(y_i = \text{"spam"} \mid x_{i1}, x_{i2}, \ldots, x_{id}) = \frac{p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"})\, p(y_i = \text{"spam"})}{p(x_{i1}, x_{i2}, \ldots, x_{id})}$$

- $p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{“spam”})$ is probability that spam has features x_i.



$$p(x_{i1}, x_{i2}, \ldots, x_{id} \mid y_i = \text{"spam"}) = \frac{\#\text{ spam messages with features } x_i}{\#\text{ spam messages}}$$

- Also hard to approximate.
  - And we need it.

Naïve Bayes

- Naïve Bayes makes a big assumption to make things easier:

$$p(\text{hello}=1, \text{vicodin}=0, 340=1 \mid \text{spam}) \approx p(\text{hello}=1 \mid \text{spam})\, p(\text{vicodin}=0 \mid \text{spam})\, p(340=1 \mid \text{spam})$$

HARD

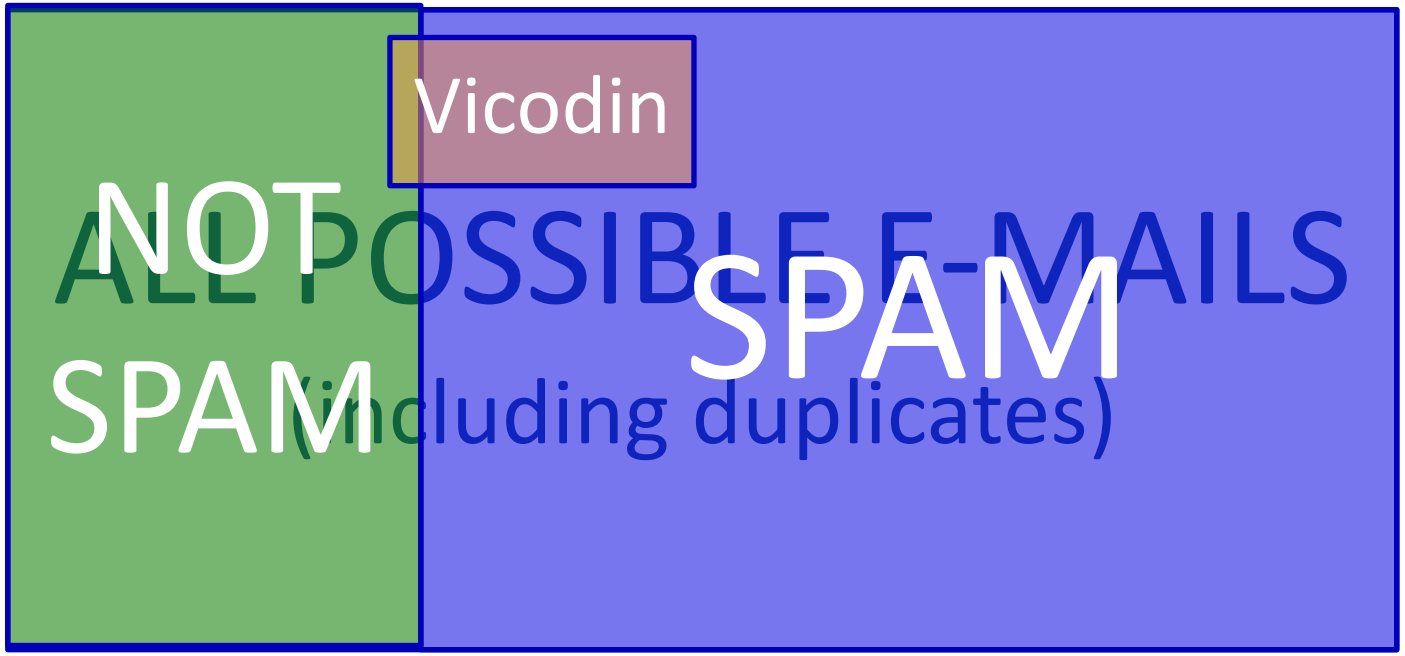
easy easy easy

- We assume *all* features x_i are conditionally independent give label y_i.
  - Once you know it's spam, probability of "vicodin" doesn't depend on "340".
  - Definitely not true, but sometimes a good approximation.

- And now we only need easy quantities like p("vicodin" = 0| y_i = "spam").

Naïve Bayes

- p("vicodin" = 1 | "spam" = 1) is probability of seeing "vicodin" in spam.



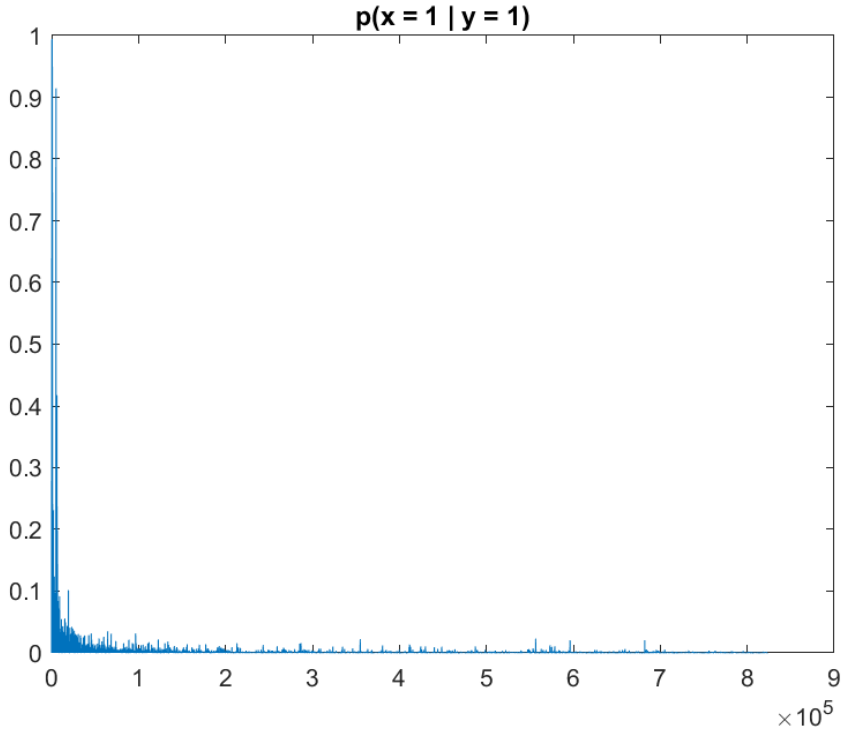
- Easy to estimate:

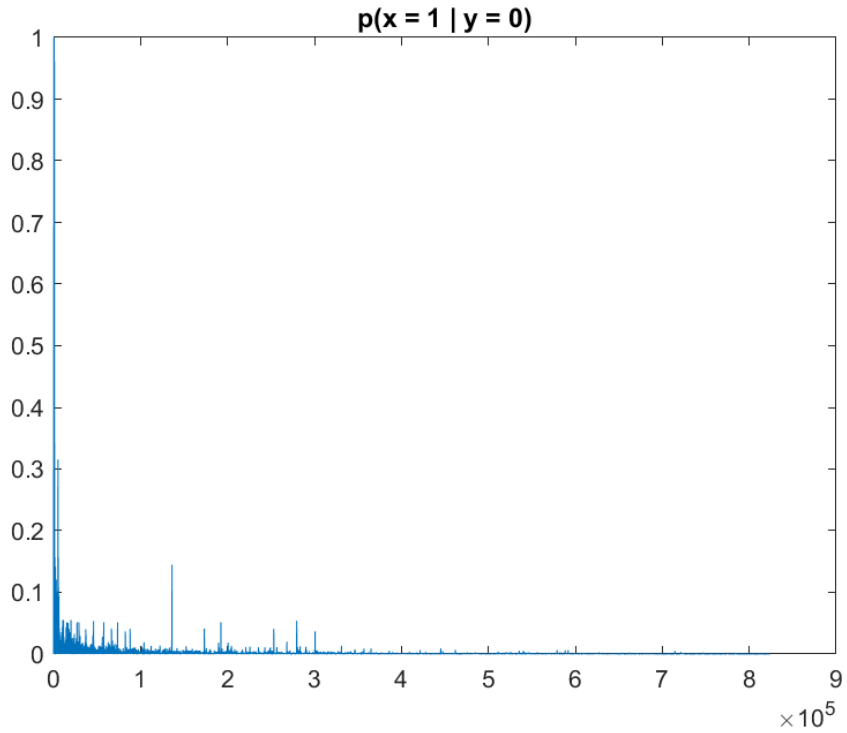
$$p(\text{vicodin}=1 \mid \text{spam}=1) = \frac{\#\text{ spam messages w/ vicodin}}{\#\text{ spam messages}}$$

Again, this is a "maximum likelihood estimate" (MLE). We will cover how to derive this later.

Naïve Bayes

- Comparing p(x | y = c) for “spam” and “not spam”:





- Even though independence is not true, these values may be enough to distinguish the classes.

Summary

- Optimization bias: using a validation set too much overfits.
- Cross-validation: allows better use of data to estimate test error.
- No free lunch theorem: there is no "best" ML model.
- Probabilistic classifiers: try to estimate $p(y_i \mid x_{i1}, x_{i2},\ldots,x_{id})$.
- Naïve Bayes: simple probabilistic classifier based on counting.
  - Uses conditional independence assumptions to make training practical.

- Next time:
  - A "best" machine learning model as 'n' goes to ∞.

Back to Decision Trees

- Instead of validation set, you can use CV to select tree depth.

- But you can also use these to decide whether to split:
  - Don't split if validation/CV error doesn't improve.
  - Different parts of the tree will have different depths.
- Or fit deep decision tree and use [cross-]validation to prune:
  - Remove leaf nodes that don't improve CV error.

- Popular implementations that have these tricks and others.

Random Subsamples

- Instead of splitting into k-folds, consider "random subsample" method:
  - At each "round", choose a random set of size 'm'.
    - Train on all examples except these 'm' examples.
    - Compute validation error on these 'm' examples.
- Advantages:
  - Still an unbiased estimator of error.
  - Number of "rounds" does not need to be related to "n".
- Disadvantage:
  - Examples that are sampled more often get more "weight".

Cross-Validation Theory

- Does CV give unbiased estimate of test error?
  - Yes!
    - Since each data point is only used once in validation, expected validation error on each data point is test error.
  - But again, if you use CV to select among models then it is no longer unbiased.

- What about variance of CV?
  - Hard to characterize.
  - CV variance on ‘n’ data points is worse than with a validation set of size ‘n’.
    - But we believe it is close.

- Does cross-validation remove optimization bias?
  - No, but the bias might be smaller since you have more “test” points.

Handling Data Sparsity

- Do we need to store the full bag of words 0/1 variables?
  - No: only need list of non-zero features for each e-mail.

$	Hi	CPSC	340	Vicodin	Offer	…
1	1	0	0	1	0	…
0	0	0	0	1	1	…
0	1	1	1	0	0	…
1	1	0	0	0	1	…

VS.

Non-Zeroes
{1,2,5,…}
{5,6,…}
{2,3,4,…}
{1,2,6,…}

  - Math/model doesn't change, but more efficient storage.

“Best” and the “Good” Machine Learning Models

- Question 1: what is the “best” machine learning model?
  - The model that gets lower generalization error than all other models.
- Question 2: which models always do better than random guessing?
  - Models with lower generalization error than “predict 0” for all problems.

- No free lunch theorem:
  - There is **no** “best” model achieving the best generalization error for every problem.
  - If model A generalizes better to new data than model B on one dataset, there is another dataset where model B works better.

No Free Lunch Theorem

- Let's show the "no free lunch" theorem in a simple setting:
  - The x^i and y^i are binary, and y^i being a deterministic function of x^i.
- With 'd' features, each "learning problem" is a map from $\{0,1\}^d$ -> $\{0,1\}$.
  - Assigning a binary label to each of the 2^d feature combinations.

Feature 1	Feature 2	Feature 3
0	0	0
0	0	1
0	1	0
…	…	…

y (map 1)	y (map 2)	y (map 3)	…
0	1	0	…
0	0	1	…
0	0	0	…
…	…	…	…

- Let's pick one of these 'y' vectors ("maps" or "learning problems") and:
  - Generate a set training set of 'n' IID samples.
  - Fit model A (convolutional neural network) and model B (naïve Bayes).

No Free Lunch Theorem

- Define the "unseen" examples as the (2^d – n) not seen in training.
  - Assuming no repetitions of x^i values, and $n < 2^d$.
  - Generalization error is the average error on these "unseen" examples.
- Suppose that model A got 1% error and model B got 60% error.
  - We want to show model B beats model A on another "learning problem".

- Among our set of "learning problems" find the one where:
  - The labels y^i agree on all training examples.
  - The labels y^i disagree on all "unseen" examples.
- On this other "learning problem":
  - Model A gets 99% error and model B gets 40% error.

Proof of No Free Lunch Theorem

- Further, across all "learning problems" with these 'n' examples:
  - Average generalization error of **every** model is 50% on unseen examples.
    - It's right on each unseen example in exactly half the learning problems.
  - With 'ℓ' classes, the average error is (ℓ-1)/ℓ (random guessing).

- This is kind of depressing:
  - For general problems, no "machine learning" is better than "predict 0".

- But the proof also reveals the problem with the NFL theorem:
  - Assumes every "learning problem" is equally likely.
  - World encourages patterns like "similar features implies similar labels".
